Abstract
We address the problem of representing dynamic graphs using $k^2$-trees. The $k^2$-tree data structure is one of the succinct data structures proposed for representing static graphs, and binary relations in general. It relies on compact representations of bit vectors. Hence, by relying on compact representations of dynamic bit vectors, we can also represent dynamic graphs. In this paper we follow instead the ideas by Munro et al., and we present an alternative implementation for representing dynamic graphs using $k^2$-trees. Our experimental results show that this new implementation is competitive in practice.

Introduction

Graphs are ubiquitous among many complex systems, where we find large and dynamic complex networks. It is therefore important to be able to not only store such graphs in compressed form, but also to update and query them efficiently while compressed. Most succinct data structures for representing graphs are however static [1, 2]. And only recently, by relying on compact representations of dynamic bit vectors, succinct representations for dynamic graphs were presented [3]. These representations suffer however from a well known bottleneck in compressed dynamic indexing [4, 5]. In this paper we adopt the ideas proposed by Munro et al. [4] to represent dynamic graphs through collections of static and compact graph representations.

Our approach relies on $k^2$-trees to represent static graphs and our implementation supports both edge insertions and deletions with almost the same (but amortized) cost as static $k^2$-trees. We provide an implementation and an extensive experimental evaluation.

From static $k^2$-trees to dynamic graphs

Let $G = (V, E)$ be a graph where $V$ is the set of vertices, with size $n$, and $E \subseteq V \times V$ is the set of edges, with size $m$. The main idea is to represent $G$ dynamically, supporting edge insertions and deletions, as well as common operations over graphs, through a
collection of static edge sets \( C = \{ E_0, \ldots, E_r \} \). Each static edge set \( E_i \) is then represented using a static \( k^2 \)-tree, except \( E_0 \) which is represented through a dynamic and uncompressed adjacency list.

As discussed by Munro et al. [4], we must control both the number of edges \( m_i \) in each set \( E_i \) and the number \( r \) of such sets to achieve the optimal amortized cost for each operation. The first set \( (E_0) \) contains at most \( m / \log^2 m \) elements. In general we require that \( m_i \) is at most \( m / \log^{2-i} m \), for some constant \( \varepsilon > 0 \). We must also have that \( m_r = m / \log^{2-r\varepsilon} m \leq m \), which implies that \( r \leq 2/\varepsilon \), when \( m \) is at least 3. When \( \varepsilon \) is a fixed constant so is \( r \). For example when \( \varepsilon = 1/4 \) we get that \( r \) is at most \( 2/(1/4) = 8 \). Hence the maximum number of edges per static set follows a geometric progression. Whenever we reach the maximum for a given set \( E_i \), we find a set \( E_j \), with \( i < j \leq r \) such that \( \sum_{\ell=0}^j m_\ell \leq m / \log^{2-j\varepsilon} m \) and (re)build \( E_j \) with all edges in it and in the previous sets, and reset all previous sets. We detail this process below.

**Space**

Let us analyse the required space to represent the data structure. The set \( E_0 \) is represented in an uncompresses adjacency list coupled with a hash table to allow answering queries on edge existence in constant time. If we use also a hash table to store the adjacency lists, then we need \( O(m_0 \log m_0 + m_0 \log n) \) bits, where \( m_0 \leq m / \log^2 m \) is the number of edges in \( E_0 \). Each set \( E_i \), for \( 1 \leq i \leq r \), is represented in a static \( k^2 \)-tree and it requires \( k^2 m_i (\log_{k^2}(n^2/m_i) + O(1)) \) bits [2], where \( m_i \leq m / \log^{2-i\varepsilon} m \). Hence, overall, the space required is

\[
O(m_0 \log m_0 + m_0 \log n) + \sum_{i=1}^r k^2 m_i (\log_{k^2}(n^2/m_i) + O(1))
\]  

(1)

bits. The first term in Equation 1 can be written as \( O((m / \log^2 m)(\log m + \log n)) = O(m / \log n) \). To bound the second term we essentially need to sum a geometric sequence, we will assume \( m_i = m / \log^{2-i\varepsilon} m \) as this is the case that requires more space. First let us sum the \( m_i \) values,

\[
\sum_{i=1}^r m_i = m_1 \sum_{i=1}^r (\log^\varepsilon m)^{i-1} = m_1 \frac{(\log^\varepsilon m) - 1}{(\log^\varepsilon m) - 1}.
\]  

(2)

Notice that as \( m \) grows the logarithms dominate the values in the fraction which therefore approximates \( (\log^\varepsilon m) / \log^\varepsilon m \). This expression can be further upper bounded by \( (\log^2 m) / \log^\varepsilon m \), because of the relation between \( r \) and \( \varepsilon \). Hence the overall bound is the relation \( \sum_{i=1}^r m_i \leq m_1 (\log^2 m) / \log^\varepsilon m = m \)

Now for the complete formula we obtain an upper bound by noticing that \( m_i \geq m_0 \) for all \( i \). The deduction is the following:

\[
\sum_{i=1}^r k^2 m_i (\log_{k^2}(n^2/m_i) + O(1)) \leq \sum_{i=1}^r k^2 m_i (\log_{k^2}(n^2/m_0) + O(1))
\]

\[
= k^2 \left( \log_{k^2}(n^2/m_0) \left( \sum_{i=1}^r m_i \right) + O(r) \right) \leq k^2 \left( m \log_{k^2}(n^2/m_0) + O(1/\varepsilon) \right)
\]
\[
\leq k^2 \left( (m (2 \log \log n) + \log_{k^2}(n^2/m)) + O(1/\varepsilon) \right).
\]

A tighter bound can be obtained by noticing that the largest terms in the sum are the last ones. Hence essentially \(m_r\) takes the role of \(m_0\) in the previous expression, yielding an \(\varepsilon \log \log n\) term instead of a \(2 \log \log n\) term, which is expected to be reasonably small.

Therefore, the overall space in bits is bounded by \(k^2 m (\log_{k^2}(n^2/m) + 2 \log \log n) + O(k^2/\varepsilon) + o(m)\).

**Insertion, deletion and queries**

We rely on efficient set operations over \(k^2\)-trees [6]. Given \(C\) and \(C'\) represented as two \(k^2\)-trees, we are able to compute \(k^2\)-trees representing \(C \cup C'\), \(C \cap C'\) and \(C \setminus C'\) in linear time on the size |\(C\)| and |\(C'\)| of the representations. Moreover these operations are done without uncompressing \(C\) and \(C'\), with only some negligible extra space being used.

Insertion works as follows. Given a new edge \((u, v)\),

1. If |\(E_0\)| < \(m_0\), then just add \((u, v)\) to \(E_0\) and we are done.

2. Otherwise, build a \(k^2\)-tree for \(E_0\), find \(0 < j \leq r\) such that \(\sum_{i=0}^j m_i \leq m_j\), and rebuild \(E_j\) with all edges in \(E_0, \ldots, E_j\) by successive unions of \(k^2\)-trees.

If |\(E_0\)| < \(m_0\), then insertion takes constant time since we are relying on an adjacency list coupled with a hash table to maintain adjacencies, as described before. Otherwise, we need to build a \(k^2\)-tree for \(E_0\) and find some \(E_j\) to accommodate all previous collections \(E_i\), for \(0 \leq i \leq j\). Note that the construction of the \(k^2\)-tree for \(E_0\) takes \(O(m_0 \log_k n)\) time [2], and the pairwise union of at most \(j\) \(k^2\)-trees representing collections \(E_0, \ldots, E_{j-1}\) takes \(O(m_j \log_k n)\) time, using only the required space to store a \(k^2\)-tree representing \(E_j\). The amortized analysis of the insertion cost follows the argument presented by Munro et al. [4] for the general case. Either \(E_j\) is new and \(m\) has at least doubled, in which case the amortized cost is \(O(\log_k n)\) per edge insertion, or \(E_j\) is not new and we are adding to it all edges in collections \(E_0, \ldots, E_{j-1}\). In this last case the building cost can be imputed to the new edges added to \(E_j\), which are at least \(m_{j-1} = m_j/\log^\varepsilon m\). Therefore, the amortized cost of inserting an edge in \(E_j\) is \(O(\log_k n \log^\varepsilon m)\) and, since each link can be moved once to each \(E_j\), with \(0 < j \leq r = \lceil 2/\varepsilon \rceil\), the amortized cost of inserting an edge is \(O(\log_k n \log^\varepsilon m(1/\varepsilon))\). And this is then the overall amortized cost of inserting an edge.

Deletion works as follows. Given an edge \((u, v) \in E\),

1. If \((u, v) \in E_0\), then just remove it and we are done.

2. Otherwise, find \(0 < j \leq r\) such that \((u, v) \in E_j\) and, if there is such \(j\), set the corresponding bit to zero in \(E_j\) \(k^2\)-tree.

3. Update the number \(m'\) of deleted edges.

4. If \(m' > m / \log \log m\), rebuild \(C\).
Deleting and edge in $E_0$ takes constant time. Checking and deleting an edge in our collections takes $O((\log_k n)/\varepsilon)$, since checking if an edge exists in a given $k^2$-tree takes $O(\log_k n)$ [2], and we might have to look in each collection $E_i$, with $0 < i \leq r = \lceil 2/\varepsilon \rceil$. Once an edge is found, marking it for deletion takes constant time. The full rebuild after $m/\log \log m$ edges are deleted costs $O(m \log_k n)$, i.e., it has an amortized cost of $O((\log_k n \log \log m))$ per deleted edge. Overall deleting an edge has then an amortized cost of $O((\log_k n)/\varepsilon + \log_k n \log \log m)$.

Querying works just as in $k^2$-trees with the difference that we need to query all sets in the collection. Therefore, the querying cost increases by a factor of $O(1/\varepsilon)$.

Comparison with other constructions

Given a graph $G$, for a fixed $\varepsilon$, the presented data structure uses essentially the same space as a static $k^2$-tree, and it supports insertions and deletions in $O(\log_k n \log^2 m)$ and $O(\log_k n \log m)$ time, respectively. The implementation of dynamic $k^2$-trees using dynamic bit vectors [3] requires a small space overhead, and it supports insertions and deletions in $O(\log_k n \log n)$ time. Hence, since $m$ is $O(n^2)$, it has a slowdown by a factor of $o(\log n/\log \log n)$ with respect to the proposed data structure.

Edge queries over the proposed data structure take the same time as in static $k^2$-trees. Although dynamic $k^2$-trees using dynamic bit vectors [3] work similarly to static $k^2$-trees – in practice they replace static bit vectors for dynamic ones – they suffer a slowdown by a factor of $\Omega(\log n/\log \log n)$ [5, Chapter 12].

We compare also with a new representation, $k^2$-tries, proposed recently [7]. This data structure uses $O(m \log(n^2/m) + m \log k)$ bits, and it supports edge queries and updates in $O(\log_k n)$ amortized time. The implementation provided by $k^2$-tries authors supports only edge additions and queries, with slightly worse time complexities.

Experimental analysis

We compare the dynamic $k^2$-tree implementation proposed in this paper, henceforth named sdk2tree, with the dynamic implementation dk2tree based on dynamic bit vectors [3], a static implementation k2tree [2], and also with two versions of $k^2$-tries, k2trie{1,2}, that differ only on the parametrization (trading compression for speed) [7]. All other implementations were provided by their authors, and all code is available at https://github.com/aplf/sdk2tree.

All tested implementations are written in C and compiled with gcc 6.3.0 2017-05-16 using the -O3 optimization flag. Experiments were performed on an SMP machine with 256GB of RAM and four Intel(R) Xeon(R) CPU E7-4830 @ 2.13GHz, each one with 512KB in L1 cache, 2MB in L2 cache, 24MB in L3 cache and eight cores, 64 threads in total. All implementations are single-threaded.

We implemented a common interface to test each implementation. All dynamic data structures dk2tree, sdk2tree and k2trie{1,2} are initialized empty. The static k2tree is initialized by reading the whole graph from secondary storage. Once initialized, the interface starts a main loop which reads instructions from stdin representing all supported edge operations, with additions and deletions not available in k2tree, and k2trie{1,2} supporting only edge additions and queries.
Table 1: The first four datasets were synthetically generated using a duplication model. The last five datasets are real-world Web graphs made available by the Laboratory for Web Algorithmics (LAW) [8, 9] (dataset uk-2007-05 is actually uk-2007-05-100000 in the LAW website).

Datasets and methodology

We used both real and synthetic datasets. In Table 1 we identify the datasets and their properties. For each dataset, we present its vertex and edge counts written as |V| and |E|, respectively, and the total disk space used by each implementation.

Real-world graphs were obtained from the Laboratory of Web Algorithmics [8, 9]. Synthetic datasets were generated from the partial duplication model [10]. Although the abstraction of real networks captured by the partial duplication model, and other generalizations, is rather simple, the global statistical properties of, for instance, biological networks and their topologies can be well represented by this kind of model [11]. We generated random graphs with selection probability $p = 0.5$, which is within the range of interesting selection probabilities [10]. The number of edges for those graphs is approximately 25 times the number of vertices.

We consider four major operations: edge additions, removals, querying/checking and vertex neighborhood listing. Elapsed time was measured using the clock() function. Although the k2tree implementation does not support additions, we included it in the comparison. For that we build a k2tree for each dataset and we divided the time it took by the number of edges, obtaining then the average time for edge addition. This allowed us to evaluate the overhead introduced by dynamic data structures. The removal operation is compared only between sdk2tree and dk2tree. This operation was evaluated by adding all edges and removing a sample of 50% of them. All three *k2tree implementations were directly compared for the listing operation. After adding all edges, we evaluated this operation by asking for the neighborhoods of a sample of 50% of the vertices. We measure for each implementation the average time per individual operation, the maximum resident set size (memory peak was obtained with GNU time), and the disk space taken by data structures serialization.

Figure 1: Average time taken for adding an edge in real Web graphs and in synthetic graphs (generated from a duplication model), respectively.

Figure 2: Average time taken for deleting an edge in real Web graphs and in synthetic graphs (generated from a duplication model), respectively.

Cost analysis

Let us analyse the cost of each operation over the different datasets and for the different implementations. Figure 1 shows the average running time for adding an edge. As mentioned before, we included k2tree in this comparison to observe what is the slowdown introduced by dynamic data structures. As expected, dynamic implementations take in general more time per add operation than k2tree. We can observe that k2trie{1,2} and sdk2tree are sometimes slightly faster than k2tree. The case of sdk2tree may be explained by the sparsity of the internal k²-trees. As expected also from the theoretical analysis, the add operation on sdk2tree is faster than on dk2tree, in particular for real Web graphs. Figure 2 shows the average running time for removing an edge. Across all datasets, sdk2tree was consistently faster than dk2tree. We note that costs seem to correlate well with the predicted bounds.

Figures 3 and 4 show the average running time for listing vertex neighborhoods and querying/checking edges. Across all datasets, sdk2tree was faster than dk2tree and on-par with k2tree and k2trie{1,2}. In the case of listing, we are plotting against \(O(\sqrt{m})\), the bound on the cost of listing vertex neighborhoods with k2tree [2]. This bound is valid also for sdk2tree and dk2tree as discussed previously in the theoretical analysis.

Let us now analyse how much memory is used by each implementation. In this
Figure 3: Average time taken for listing neighbors of random vertices in real Web graphs and in synthetic graphs (generated from a duplication model), respectively.

Figure 4: Average time taken for querying links in real Web graphs and in synthetic graphs (generated from a duplication model), respectively.

analysis we will consider resident memory while we are performing operations. For the space that each data structure takes once serialized on secondary memory, we refer the reader to Table 1. Figure 5 shows the max resident memory while adding edges in dynamic implementations. We can observe that \texttt{sdk2tree} requires more memory than \texttt{dk2tree}, although the growth rate is similar. This can look unexpected given the theoretical bounds derived previously, but we must recall that we are periodically merging together static collections in the \texttt{sdk2tree} implementation. We will analyse this in more detail below.

Figure 6 shows the max resident memory while removing edges. Since we are adding all links before removing about 50\% of them, the memory requirements for \texttt{sdk2tree} are exactly the same as in Figure 5. This also means that the removing operation does not increase the space requirements in this implementation. On the other hand, the memory requirements are now higher for \texttt{dk2tree}, being more close to those of \texttt{sdk2tree}.

Figure 7 shows the max resident memory while adding edges and listing vertex neighborhoods. Since we are adding all links as before, the memory requirements for \texttt{sdk2tree} and \texttt{dk2tree} are identical to those observed in Figures 5 and 6. We included now also the \texttt{k2tree} in our analysis. Given that this last implementation requires much more space for constructing the data structure, we had to use log scale
in Figure 7. We should note however that once constructed, \texttt{k2tree} requires much less space as shown in Table 1. For instance, for the dataset \texttt{dm100K}, \texttt{k2tree} had a peak resident memory footprint of around 503.11 MB during construction, while its $k^2$-tree structure stored on disk is around 7.01 MB. It is nevertheless interesting to note that, although we are using the exact same implementation of $k^2$-trees for representing the static collections within our \texttt{sdk2tree} implementation, since we are merging those collections without decompressing them as mentioned before, we do not observe such high memory footprint while adding edges in \texttt{sdk2tree}.

Memory allocation analysis

Our implementation of the dynamic $k^2$-tree is based on the technique presented in [4], whose authors claim additional space is necessary to perform a union of two collections (which would be decompressed before the union operation taking place). The implementation we present is able to perform the union operation without decompressing the collections, effectively avoiding this pitfall. We show for dataset \texttt{uk-2007-05}, in Figure 8, a detailed analysis of heap memory usage. The analysis was performed using \texttt{valgrind}, with parameters \texttt{--tool=massif --max-snapshots=200 --detailed-freq=5}, and the visualizations using the \texttt{massif-visualizer}\textsuperscript{4}.

\textsuperscript{4}https://github.com/KDE/massif-visualizer
Figure 7: Max resident memory while listing neighbors of random vertices in real Web graphs and in synthetic graphs (generated from a duplication model), respectively.

Figure 8: valgrind heap allocation profile for dataset uk-2007-05. The label time in i in the x axis denotes the number of instructions executed.

It can be observed that during execution where edges are continuously added, there are memory peaks associated with the union operation, increasing temporarily the heap usage by at most a factor of 2. This explains also the difference in maximum resident memory between sdk2tree and dk2tree observed before in Figures 5 and 6.

Final remarks

We presented the sdk2tree implementation for representing dynamic graphs, based on the $k^2$-tree graph representation and relying on a collection of static $k^2$-trees. This makes sdk2tree a semi-dynamic data structure. Nevertheless, it supports edge additions and removals with competitive performance, showing faster execution times than the dk2tree implementation, a dynamic version of $k^2$-trees based on dynamic bit vectors, and on par with $k^2$-tries with respect to additions and queries.

Implementations like those analysed in this paper, when implemented carefully, are of crucial importance for the efficient analysis and storage of evolving graphs, while drastically reducing the requirements of secondary storage compared to traditional dynamic graph representations. Hence, as future work, we envision further refinements to these data structures to achieve greater efficiency, namely in what concerns
listing vertex neighborhoods, in order to produce usable libraries for the analyses of large evolving graphs. We are aiming also to research how these representations may be used within distributed graph processing systems in order to reduce the memory pressure observed often in these systems.
